Dry-etched silicon-on-insulator waveguides with low propagation and fiber-coupling losses

Dry-Etched Silicon-on-Insulator Waveguides With Low Propagation and Fiber-Coupling Losses

Kimmo Solehmainen, Timo Aalto, James Dekker, Markku Kapulainen, Mikko Harjanne, Kaupo Kukli, Päivi Heimala, Kai Kolari, and Markku Leskelä

Abstract—Optical rib waveguides with various widths and heights were fabricated on silicon-on-insulator (SOI) substrates. Silicon etching was based on dry etching with inductively coupled plasma (ICP)-type reactive ion etcher. The etching process was developed to ensure low optical losses. Propagation loss of 0.13 $\pm$ 0.02 dB/cm was measured for the fundamental mode at the wavelength of 1550 nm in a curved 114-cm-long waveguide. The reflection losses were suppressed by applying atomic layer deposition (ALD) in the growth of antirefection coatings (ARCs).

Index Terms—Atomic layer deposition (ALD), integrated optics, optical device fabrication, optical losses, optical waveguides, silicon-on-insulator (SOI) technology.

I. INTRODUCTION

The aim of integrated optics technology is to realize a variety of different optical components on a single chip. As a consequence of the mature and widespread state of silicon-based technology, Si substrate has served as a base for many different waveguide material systems used in integrated optics. These include, e.g., silica [1], [2], germanium [3], silicon oxynitride [4], polymers [5], and silicon-on-insulator (SOI) [6]–[11]. Also III–V semiconductors have been structured on silicon [12]. One of the main advantages of SOI waveguides is the possibility for a size reduction of integrated optical structures. This results from the high refractive index of silicon, setting a high index contrast between the silicon core and the surrounding oxide cladding. Another strong motivation to study such structures has risen from the desire to monolithically integrate SOI-based optical components and control electronics.

The fabrication of single-mode SOI waveguides with low propagation losses ($\sim$ 0.1 dB/cm) has been demonstrated using a wet silicon-etching process [7]. The production of functional integrated optical components using wet etching is difficult due to the modest critical dimension control. Dry etching offers the required anisotropic etch profile and is therefore preferred in practical applications. However, achieving low-loss SOI waveguides with dry etching is not straightforward because of the surface roughness produced on the exposed sidewalls. The surface-roughness-induced scattering of light is the key factor determining the optical losses present in the SOI waveguide. In this work, a fabrication process based on dry silicon etching was developed to produce low-loss SOI waveguides. Waveguide test structures were designed to enable accurate determination of the optical loss.

The SiO$_2$/Si interface present at the fiber/waveguide connection reflects 16% of the incoming light intensity, if the possible airgap is ignored. Two waveguide connections produce reflection losses of 28% (1.45 dB), which has the same order of magnitude as the other loss components present in the waveguide. The reflection losses can be reduced with an antireflection coating (ARC). Typically, this is done by sputtering layers of suitable material on the end facets after the chip is diced and polished. Atomic layer deposition (ALD) is a promising technique for the realization of optical coatings [13]. In ALD, the film is grown in a sequential manner, which basically offers nanometer accuracy in thickness control. Since ALD offers an even growth regardless of the surface shape, it enables the preparation of high-quality optical coatings also on vertical sidewalls. Thus, ALD could be used for deposition of the ARC as a wafer-level-process step, instead of being a chip-level process. In this study, the feasibility of ALD in preparation of ARCs was tested by depositing tantalum pentoxide Ta$_2$O$_5$ films on polished waveguide-end facets.

II. WAVEGUIDE FABRICATION

The formation of SOI waveguides is relatively simple compared to, e.g., silica-on-silicon technology, since growth of the active layer is avoided. The necessary processing steps include only the mask patterning, silicon etching, and cladding oxide deposition. In this study, a 300-nm SiO$_2$ film was used beneath the resist as an additional hard mask layer. The purpose of the SiO$_2$ mask was to ensure the protection of the patterned structures during the Si etching. The SiO$_2$ deposition was done with a low-temperature-oxide (LTO) process in a low-pressure chemical-vapor-deposition (LPCVD) furnace. Waveguide patterns were transferred to the oxide mask using standard photolithography and dry oxide etching in a parallel-plate plasma etcher. Silicon etching was done using an inductively coupled plasma (ICP)-type reactive ion etcher provided by Surface Technology Systems (STS). In order to minimize the surface roughness caused by the etching step, the etching process was modified from the STS advanced silicon etch (ASE) process [14]. In the ASE process, the sidewall passivation and
The final step in the waveguide fabrication was the deposition of plasma stripping and wet chemical etching, respectively. The resist residuals and the oxide mask were removed with oxygen processes shown in Fig. 1(b). After the silicon etching, the ASE process is higher than in the continuous passivation. However, the degree of random surface roughness of waveguide cross-section along the direction of light propagation. The alternating etching and passivation steps of (SEM) images of the waveguide sidewalls etched with both processes. The etch-depth variation over the wafer was measured with a profilometer as ±7%. The etch selectivity against the AZ5214 resist was measured as 8:1, while the selectivity against SiO$_2$ was 13:1. The selectivities were significantly lower than in the typical ASE process because of the continuous passivation. In terms of surface roughness, the advantage of the continuous-passivation etch process over the standard ASE process can be seen in Fig. 1. The figure shows scanning-electron-microscope (SEM) images of the waveguide sidewalls etched with both processes. The alternating etching and passivation steps of the ASE process result in an undulated sidewall, as shown in Fig. 1(a). In principle, this undulation does not change the waveguide cross-section along the direction of light propagation. However, the degree of random surface roughness of the ASE process is higher than in the continuous-passivation process shown in Fig. 1(b). After the silicon etching, the resist residuals and the oxide mask were removed with oxygen plasma stripping and wet chemical etching, respectively. The final step in the waveguide fabrication was the deposition of a 1-µm top-cladding oxide layer by wet thermal oxidation at 1050 °C.

The test structures in the mask included 114-cm-long waveguides with various widths. The long waveguides were fitted to the 10-cm wafer by constructing them in a spiral form, as seen in Fig. 2. As there were several waveguides traveling in parallel in the spiral, each waveguide passed through 100 waveguide crossings. The bending radius of these waveguides varied between 2 and 11 µm. The lithography process and the thermal oxidation change the waveguide dimensions from the nominal values. The dimensions given in the text below are actual dimensions after the processing, verified with an optical microscope.

### III. Propagation-Loss Measurements

Soref et al. [11] have proposed a formula for the waveguide dimensions that lead to single-mode operation in rib-type waveguides. The waveguide geometry was of rib type (Fig. 3), which can confine large optical modes without sacrificing single-mode operation [11]. The waveguide core defined by the rib has thickness $H$ and width $W$. The thickness of the slab surrounding the rib is $h$. The buried oxide layer (BOX) in the SOI wafers was used was 1–3-µm thick. Three different SOI layer thicknesses were tested as a substrate, resulting in different waveguide thicknesses. A bond and etch-back SOI (BESOI) wafer yielded $H = 9$ µm (BOX = 1 µm). SOI layers of $H = 5$ µm (BOX = 3 µm) and $H = 2$ µm (BOX = 3 µm) were formed by epitaxially growing silicon on initially 1-µm thick smart-cut SOI wafers. The SOI thickness variation was measured to be ±0.5 µm for BESOI wafers and ±0.05 µm for the epitaxially thickened smart-cut wafers. The resistivity of the SOI layers was 1500–3500 Ωcm. For the waveguides studied here, such a high resistivity results in negligible absorption losses compared to the scattering losses. The etch depth $H-h$ was varied in different samples, so that the ratio $h/H$ varied between 0.5 and 0.4. The waveguide width in the mask varied between 2 and 11 µm. The lithography process and the thermal oxidation change the waveguide dimensions from the nominal values. The dimensions given in the text below are actual dimensions after the processing, verified with an optical microscope.
straight waveguides:

\[
\frac{W}{H} \leq 0.3 + \frac{h}{\pi} \sqrt{1 - \left(\frac{h}{W}\right)^2}.
\]  

(1)

The formula is applicable when \(h/H \geq 0.5\). For the curved waveguides presented here, Soref’s formula cannot be directly applied. An immediate contradiction comes from the fact that \(h/H\) was often made slightly less than 0.5 in order to minimize the bending losses. With such a slight deviation from Soref’s condition, however, it is expected that one could estimate the approximate single-mode limit using the formula. This assumption has also been verified with simulations [6], [15]. Another discrepancy comes from the fact that in a curved waveguide, single-mode operation can be achieved with dimensions that would cause the corresponding straight waveguide to be multimoded. With an appropriate bending radius, the bending losses in a curved waveguide can be very high for the weakly guided higher order modes, while still very small for the fundamental mode. In that case, the curved waveguide is, in practice, single-moded, and the loss of the fundamental mode can be measured. In this study, the single-mode/multimode behavior was determined experimentally by monitoring the output of the waveguide with an IR camera while moving the input fiber in the vicinity of the waveguide input. With a waveguide showing single-mode behavior, the movement away from the optimal input-fiber alignment generates symmetrical intensity attenuation at the output, while the shape of the output intensity distribution is not changed. However, in the case of a multi-mode waveguide, such an input change results in variations in the output intensity distribution, which can be detected with the camera.

For the propagation-loss measurements, the waveguide ends were diced and polished to optical quality. In the measurement, unpolarized light from a broadband light source was coupled into another single-mode fiber. Transmitted light was coupled into the waveguide with a single-mode fiber. The propagation-loss spectrum was measured in the waveguide with an optical spectrum analyzer, the transmission spectrum could be directly butt coupling the input and output fibers. The overlap integrals between them. For the fiber, a Gaussian field distribution with 1/e field radius of 5 \(\mu\)m was assumed. The modal coupling loss due to two fiber couplings was simulated as 2.5 dB, yielding the propagation loss of 0.13 dB/cm. The length of the waveguides enabled accurate determination of the propagation loss, since coupling losses, which are typically difficult to estimate accurately, had only a small contribution to the result. Furthermore, the quality of the edge polishing had little effect on the results. The error in the loss measurement was estimated as \(\pm 0.02\) dB/cm, which is significantly more accurate than \(\pm 0.3–0.5\) dB/cm, typical to previous studies of SOI waveguide propagation loss [7]–[9].

As other loss components, such as misalignment loss, bending loss, and losses due to the waveguide crossings are neglected, this propagation-loss figure can be taken as a worst case approximation. The measured losses correspond to the fundamental mode only, as higher order modes had very high radiation losses along the curved waveguide. The disappearance of the higher order modes at the waveguide output was confirmed with the IR camera. After measuring several spiral waveguide chips and examining the propagation losses as a function of waveguide width, a pit-shape behavior similar to that of Fig. 4 was noticed. This behavior is consistent with previous SOI waveguide-loss studies [8]–[10]. With narrower waveguides, the intensity distribution is closer to the waveguide walls, increasing the scattering losses. As the width increases, it is expected that power leakage from the fundamental mode into the lossy higher order modes will be increased. If Soref’s formula were to be applied to the curved waveguide in Fig. 4, the width limit for single-mode operation would be \(W \leq 7.2\) \(\mu\)m. This limit was confirmed with simulations for both straight and bent waveguides [6], [15]. The results suggest that propagation losses around 0.1 dB/cm can be achieved in single-mode straight waveguides with the current processing technology. This is the lowest propagation loss published so far in the literature for a dry-etched SOI waveguide.

The propagation-loss spectrum was measured in the wavelength range of 1150–1650 nm for three waveguides with different thicknesses. The dimensions of these waveguides are shown in Table I. Because of higher losses, the measurements had to be performed on 7-cm-long straight waveguides for the waveguides with \(H = 5.0\) and 2.0 \(\mu\)m. The results are shown in Fig. 5. As seen in the figure, the propagation loss increases
significantly as the waveguide thickness is decreased. This is a result of increased sensitivity to surface roughness with smaller waveguide dimensions. The fabrication process was optimized only for approximately 10-μm-thick SOI waveguides. Therefore, the propagation losses of thinner SOI waveguides are expected to decrease by further process optimization. As the waveguide dimensions decrease, spectra are also prone to distortions. The periodic fluctuations are probably due to interruptions in the waveguide structure originating from the fabrication process. As expected, below 1200 nm, the material absorption of Si increases the optical losses rapidly, making the material opaque. As long as the propagation losses caused by the waveguide structure are kept low, the Si material itself allows the use of a wide wavelength range from approximately 1.3 to 4 μm [16].

IV. ANTIREFLECTION COATING (ARC)

One of the main issues in any integrated optical-waveguide technology is the connection between the waveguide and an optical fiber, resulting in reflection, modal coupling, and fiber misalignment losses. In order to eliminate the reflection losses at the interface between the Si waveguide and an optical fiber, Ta₂O₅ ARCs were deposited with ALD on the waveguide-end facets. Ta₂O₅ was chosen as the antireflection material because it is transparent at the wavelengths of interest and its refractive index is known to be close to the optimum, which is 2.26 for the SiO₂/Si interface. The ALD apparatus used here was not designed for the wafer-level processing. Therefore, the deposition was done on the waveguide chips after polishing the chip facets. Amorphous Ta₂O₅ coatings were deposited at a temperature of 300 °C from Ta(OC₅H₇)₅ and H₂O [17] using 6500 growth cycles. A FilmTek 4000 fiber-optic-based spectrophotometer from Scientific Computing International was used to measure

V. CONCLUSION

The fabrication of low-loss dry-etched silicon-on-insulator (SOI) rib waveguides was described. Propagation loss of $0.13 \pm 0.02$ dB/cm was measured at 1550 nm for a 114-cm-long curved waveguide. The measurement accuracy was exceptionally good. This is the lowest value reported in the literature for a dry-etching-based SOI waveguide and among the lowest reported in SOI material. Spectral measurements showed that the losses remained below 0.2 dB/cm from 1230 to 1750 nm. Reflection losses of 1.4 dB present at the waveguide/fiber interface were eliminated by growing Ta$_2$O$_5$ antireflection coatings (ARCs) on waveguide-end facets with atomic layer deposition (ALD).
